(a) For $\rho$ in g cm$^{-3}$.

23.2. Ionization energy loss by heavy particles [4-1]

Moderately relativistic charged particles other than electrons lose energy in matter primarily by ionization. The mean rate of energy loss (or stopping power) is given by the Bethe-Bloch equation,

$$\frac{dE}{dx} = \frac{K}{Z} \frac{1}{A} \left[ \frac{1}{\beta^2} \ln \frac{2m_e c^2 \beta^2 \gamma T_{\text{max}}}{\beta^2 - \delta^2} \right].$$

(23.1)

Here $T_{\text{max}}$ is the maximum kinetic energy which can be imparted to a free electron in a single collision, and the other variables are defined in Table 23.1. The units are chosen so that $dx$ is measured in mass per unit area, e.g., in g cm$^{-2}$.

In this form, the Bethe-Bloch equation describes the energy loss of pions in a material such as copper to about 1% accuracy for energies between about 6 MeV and 6 GeV (momenta between about 40 MeV/c and 6 GeV/c). At lower energies “C/Z” corrections for tightly-bound atomic electrons and other effects must be made, and at higher energies radiative effects begin to be important. These limits of validity depend on both the effective atomic number of the absorber and the mass of the slowing particle. Low-energy effects will be discussed in Sec. 23.2.2.

The function as computed for muons on copper is shown by the solid curve in Fig. 23.1, and for pions on other materials in Fig. 23.3. A minor dependence on $M$ at the highest energies is introduced through $T_{\text{max}}$, but for all practical purposes in high-energy physics $dE/dx$ in a given material is a function only of $\beta$. Except in hydrogen, particles of the same velocity have very similar rates of energy loss in different materials; there is a slow decrease in the rate of energy loss with increasing $Z$. The qualitative difference in stopping power behavior at high energies between a gas (He) and the other materials shown in Fig. 23.3 is due to the density-effect correction, $\delta$, discussed below. The stopping power functions are characterized by broad minima whose position drops from $\beta\gamma = 3.5$ to 3.0 as $Z$ goes from 7 to 100. The values of minimum ionization as a function of atomic number are shown in Fig. 23.2.

![Fig. 23.1: Stopping power (= -(dE/dx)) for positive muons in copper as a function of $\beta\gamma = p/Mc$ over nine orders of magnitude in momentum (12 orders of magnitude in kinetic energy)](image)
Passage of particles through matter

be minimum ionizing particles, or mip’s. Since
\(dE/dx = \gamma\) GeV (above which radiative effects dominate).

In practical cases, most relativistic particles (e.g., cosmic-ray muons) have energy loss rates close to the minimum, and are said to be minimum ionizing particles, or mip’s.

For a particle with mass \(M\) and momentum \(M\beta\gamma c\), \(T_{\max}\) is given by
\[
T_{\max} = \frac{2m_e c^2 \beta^2 \gamma^2}{1 + 2\gamma m_e/M + (m_e/M)^2}.
\]

It is usual \([4,5]\) to make the “low-energy” approximation \(T_{\max} = 2m_e c^2 \beta^2 \gamma^2\), valid for \(2\gamma m_e/M \ll 1\); this, in fact, is done implicitly in many standard references. For a pion in copper, the error thus introduced into \(dE/dx\) is greater than 6% at 100 GeV. The correct expression should be used.

At energies of order 100 GeV, the maximum 4-momentum transfer to the electron can exceed 1 GeV/c, where structure effects significantly modify the cross sections. This problem has been investigated by J.D. Jackson \([6]\), who concluded that for hadrons (but not for large nuclei) corrections to \(dE/dx\) are negligible below energies where radiative effects dominate. While the cross section for rare hard collisions is modified, the average stopping power, dominated by many softer collisions, is almost unchanged.

“The determination of the mean excitation energy is the principal non-trivial task in the evaluation of the Bethe stopping-power formula” \([7]\). Recommended values have varied substantially with time. Estimates based on experimental stopping-power measurements for protons, deuterons, and alpha particles and on oscillator-strength distributions and dielectric-response functions were given in ICRU 37 \([8]\). These values, shown in Fig. 23.5, have since been widely used. Machine-readable versions can also be found \([9]\). These values are widely used.

23.2.1. The density effect: As the particle energy increases, its electric field flattens and extends, so that the distant-collision contribution to Eq. (23.1) increases as \(\ln \beta\gamma\). However, real media become polarized, limiting the field extension and effectively truncating this part of the logarithmic rise \([10,11–14]\). At very high energies,
\[
\delta/2 \rightarrow \ln (\hbar \omega_p/I) + \ln \beta\gamma - 1/2,
\]
where \(\delta/2\) is the density effect correction introduced in Eq. (23.1) and \(\hbar \omega_p\) is the plasma energy defined in Table 23.1. A comparison with Eq. (23.1) shows that \(dE/dx\) then grows as \(\ln \beta\gamma\) rather than \(\ln \beta^2 \gamma^2\), and that the mean excitation energy \(I\) is replaced by the plasma energy \(\hbar \omega_p\). The ionization stopping power as calculated with and without the density effect correction is shown in Fig. 23.1. Since the plasma frequency scales as the square root of the electron density,
the correction is much larger for a liquid or solid than for a gas, as is
illustrated by the examples in Fig. 23.3.

The density effect correction is usually computed using Stern-
heimer’s parameterization [11]:

\[ \delta = \begin{cases} 
2(\ln 10)x - C & \text{if } x \geq x_1; \\
2(\ln 10)x - C + a(x_1 - x)^k & \text{if } x_0 \leq x < x_1; \\
0 & \text{if } x < x_0 \text{ (nonconductors)}; \\
\delta_010^{2(x-x_0)} & \text{if } x < x_0 \text{ (conductors)} 
\end{cases} \]

(23.4)

Here \( x = \log_{10} \eta = \log_{10}(p/Mc) \). \( C \) (the negative of the C used in Ref. 11) is obtained by equating the high-energy case of Eq. (23.4) with the limit given in Eq. (23.3). The other parameters are adjusted to
give a best fit to the results of detailed calculations for momenta below \( Mc \exp(x_1) \). Parameters for elements and nearly 200 compounds and mixtures of interest are published in a variety of places, notably in Ref. 14. A recipe for finding the coefficients for nontabulated materials is given by Sternheimer and Peierls [13], and is summarized in Ref. 1.

The remaining relativistic rise can be attributed to large energy transfers to a few electrons. If these escape or are otherwise accounted for separately, the energy deposited in an absorbing layer (in contrast to the energy lost by the particle) approaches a constant value, the Fermi plateau (see Sec. 23.2.5 below). At extreme energies (e.g., > 332 GeV for muons in iron), radiative effects are more important than ionization losses. These are especially relevant for high-energy muons, as discussed in Sec. 23.6.

23.2.2. Energy loss at low energies: A shell correction \( C/Z \) is often included in the square brackets of Eq. (23.1) [2,8,15] to correct for atomic binding having been neglected in calculating some of the contributions to Eq. (23.1). We show the Barkas form [15] in Fig. 23.1. For copper it contributes about 1% at \( E = 0.3 \) (kinetic energy 6 MeV for a pion), and the correction decreases very rapidly with energy.

Eq. (23.1) is based on a first-order Born approximation. Higher-order corrections, again important only at lower energy, are normally included by adding a term \( z^2L_0(\beta) \) inside the square brackets.

An additional “Barkas correction” \( z^2L_0(\beta) \) makes the stopping power for a negative particle somewhat larger than for a positive particle with the same mass and velocity. In 1956 paper, Barkas et al. noted that negative pions had a longer range than positive pions [3]. The effect has been measured for a number of negative/positive particle pairs, most recently for antiprotons at the CERN LEAR facility [16].

A detailed discussion of low-energy corrections to the Bethe formula is given in ICRU Report 49 [2]. When the corrections are properly included, the accuracy of the Bethe-Bloch treatment is accurate to about 1% down to \( \beta = 0.05 \), or about 1 MeV for protons.

For 0.01 < \( \beta < 0.05 \), there is no satisfactory theory. For protons, one usually relies on the empirical fitting formulae developed by Andersen and Ziegler [2,17]. For particles moving more slowly than \( \approx 0.01c \) (more or less the velocity of the outer atomic electrons), Lindhard has been quite successful in describing electronic stopping power, which is proportional to \( \beta \) [18,19]. Finally, we note that at low energies, e.g., for protons of less than several hundred eV, non-ionizing nuclear recoil energy loss dominates the total energy loss [2,19,20].

As shown in ICRU49 [2] (using data taken from Ref. 17), the nuclear plus electronic proton stopping power in copper is 113 MeV cm^2 g^-1 at \( T = 10 \) keV, rises to a maximum of 210 MeV cm^2 g^-1 at 100-150 keV, then falls to 120 MeV cm^2 g^-1 at 1 MeV. Above 0.5-1.0 MeV the corrected Bethe-Bloch theory is adequate.

23.2.3. Fluctuations in energy loss: The quantity \( dE/dx \delta x \) is the mean energy loss via interaction with electrons in a layer of the medium with thickness \( \delta x \). For finite \( \delta x \), there are fluctuations in the actual energy loss. The distribution is skewed toward high values (the Landau tail) [4,21]. Only for a thick layer \( (dE/dx)\delta x \gg T_{\text{max}} \) is the distribution nearly Gaussian. The large fluctuations in the energy loss are due to the small number of collisions involving large energy transfers. The fluctuations are smaller for the so-called restricted energy loss rate, as discussed in Sec. 23.2.5 below.

23.2.4. Energy loss in mixtures and compounds: A mixture or compound can be thought of as made up of thin layers of pure elements in the right proportion (Bragg additivity). In this case, \[ \frac{dE}{dx} = \sum_{j=1}^{m} w_j \frac{dE}{dx}_{ij} \] (23.5)

where \( dE/dx_{ij} \) is the mean rate of energy loss (in MeV g cm^-2) in the \( j \)th element. Eq. (23.1) can be inserted into Eq. (23.5) to find expressions for \( \langle Z/A \rangle \), (\( T \)), and (\( \delta \)); for example, \( \langle Z/A \rangle = \sum w_j Z_j/A_j = \sum w_j Z_j / \sum w_j A_j \). However, (\( T \)), as defined this way is more tightly bound than in the free elements, and (\( \delta \)) as calculated this way has little relevance, because it is the electron density which matters. If possible, one uses the tables given in Refs. 14 and 22, which include effective excitation energies and interpolation coefficients for calculating the density effect correction for the chemical elements and nearly 200 mixtures and compounds. If a compound or mixture is not found, then one uses the recipe for (\( \delta \)) given in Ref. 13 (or Ref. 23), and calculates (\( T \)) according to the discussion in Ref. 7. (Note the “\( 19\% \) rule”)

23.2.5. Restricted energy loss rates for relativistic ionizing particles: Fluctuations in energy loss are due mainly to the production of a few high-energy knock-on electrons. Practical detectors often measure the energy deposited, not the energy lost. When energy is carried off by energetic knock-on electrons, it is more appropriate to consider the mean energy loss excluding energy transfers greater than some cutoff \( T_{\text{cut}} \). The restricted energy loss rate is

\[ -\frac{dE}{dx}_{T<T_{\text{cut}}} = K \frac{Z^2}{A^2} \frac{1}{\beta^2} \frac{2}{\ln(2mc^2\beta^2T_{\text{upper}})} \frac{1}{2} \frac{2}{\ln(2mc^2\beta^2T_{\text{max}})} \]

(23.6)

where \( T_{\text{upper}} = \text{MIN}(T_{\text{cut}}, T_{\text{max}}) \). This form agrees with the equation given in previous editions of this Review [24] for \( T_{\text{cut}} < T_{\text{max}} \) but smoothly joins the normal Bethe-Bloch function (Eq. (23.1)) for \( T_{\text{cut}} > T_{\text{max}} \).

23.2.6. Energetic knock-on electrons (\( \delta \) rays): The distribution of secondary electrons with kinetic energies \( T > I \) is given by

\[ \frac{d^2N}{dT dz} = \frac{1}{2} K \frac{Z^2}{A^2} \frac{1}{T_{\text{max}}^2} \]

(23.7)

for \( I < T < T_{\text{max}} \), where \( T_{\text{max}} \) is given by Eq. (23.2). The factor \( F \) is spin-dependent, but is about unity for \( T < T_{\text{max}} \). For spin-0 particles \( F(T) = (1 - \beta^2 T / T_{\text{max}}) \); forms for spins 1/2 and 1 are also given by Rossi [4]. When Eq. (23.7) is integrated from \( T_{\text{cut}} \) to \( T_{\text{max}} \), one obtains the difference between Eq. (23.1) and Eq. (23.6). For incident

...
electrons, the indistinguishability of projectile and target means that the range of $T$ extends only to half the kinetic energy of the incident particle. Additional formulae are given in Ref. 25. Equation (23.7) is inaccurate for $T$ close to $I$: for $2I \lesssim T \lesssim 10I$, the $1/T^2$ dependence above becomes approximately $T^{-4}$, with $3 \lesssim \eta \lesssim 5$ [26].

23.2.7. Ionization yields: Physicists frequently relate total energy loss to the number of ion pairs produced near the particle’s track. This relation becomes complicated for relativistic particles due to the wandering of energetic knock-on electrons whose ranges exceed the dimensions of the fiducial volume. For a qualitative appraisal of the nonlocality of energy deposition in various media by such modestly energetic knock-on electrons, see Ref. 27. The mean local energy dissipation per local ion pair produced, $W$, while essentially constant for relativistic particles, increases at slow particle speeds [28]. For gases, $W$ can be surprisingly sensitive to trace amounts of various contaminants [28]. Furthermore, ionization yields in practical cases may be greatly influenced by such factors as subsequent recombinations [29].

23.3. Multiple scattering through small angles

A charged particle traversing a medium is deflected by many small-angle scatters. Most of this deflection is due to Coulomb scattering from nuclei, and hence the effect is called multiple Coulomb scattering. (However, for hadronic projectiles, the strong interactions also contribute to multiple scattering.) The Coulomb scattering distribution is well represented by the theory of Molière [30]. It is roughly Gaussian for small deflection angles, but at larger angles (greater than a few $\theta_0$, defined below) it behaves like Rutherford scattering, having larger tails than does a Gaussian distribution.

If we define

$$\theta_0 = \theta_{\text{rms}}^\text{plane} = \frac{1}{\sqrt{2}} \theta_{\text{rms}}^\text{space},$$

(23.8)

then it is sufficient for many applications to use a Gaussian approximation for the central 98% of the projected angular distribution, with a width given by [31, 32]

$$\theta_0 = \frac{13.6 \text{MeV}}{\beta c p} \left[ \frac{1}{x/X_0} + 0.038 \ln(x/X_0) \right].$$

(23.9)

Here $p$, $\beta c$, and $z$ are the momentum, velocity, and charge number of the incident particle, and $x/X_0$ is the thickness of the scattering medium in radiation lengths (defined below). This value of $\theta_0$ is from a fit to Molière distribution [30] for singly charged particles with $\beta = 1$ for all $Z$, and is accurate to 11% or better for $10^{-3} < x/X_0 < 100$.

Eq. (23.9) describes scattering from a single material, while the usual problem involves the multiple scattering of a particle traversing many different layers and mixtures. Since it is from a fit to a Molière distribution, it is incorrect to add the individual $\theta_0$ contributions in quadrature; the result is systematically too small. It is much more accurate to apply Eq. (23.9) once, after finding $x$ and $X_0$ for the combined scatterer.

Lynch and Dahl have extended this phenomenological approach, fitting Gaussian distributions to a variable fraction of the Molière distribution for arbitrary scatterers [32], and achieve accuracies of 2% or better.

The nonprojected (space) and projected (plane) angular distributions are given approximately by [30]

$$\frac{1}{2\pi} \exp \left( -\frac{\theta_0^2}{2\theta_0^2} \right) d\Omega,$$

(23.10)

$$\frac{1}{\sqrt{2\pi} \theta_0} \exp \left( -\frac{\theta_0^2}{2\theta_0^2} \right) d\theta_{\text{plane}},$$

(23.11)

where $\theta$ is the deflection angle. In this approximation, $\theta_0^2 \approx (\theta_{\text{space}}^2 + \theta_{\text{plane}}^2)$, where the $x$ and $y$ axes are orthogonal to the direction of motion, and $d\Omega \approx d\theta_{\text{plane}}/d\theta_{\text{plane}}$. Deflections into $\theta_{\text{plane},x}$ and $\theta_{\text{plane},y}$ are independent and identically distributed.

Figure 23.6 shows these and other quantities sometimes used to describe multiple Coulomb scattering. They are

$$y_{\text{rms}}^\text{plane} = \frac{1}{\sqrt{3}} \theta_{\text{rms}}^\text{plane} = \frac{1}{\sqrt{3}} \theta_0,$$

(23.12)

$$x_{\text{rms}}^\text{plane} = \frac{1}{\sqrt{3}} \theta_{\text{rms}}^\text{plane} = \frac{1}{\sqrt{3}} x \theta_0,$$

(23.13)

$$z_{\text{rms}}^\text{plane} = \frac{1}{4\sqrt{3}} \theta_{\text{rms}}^\text{plane} = \frac{1}{4\sqrt{3}} x \theta_0.$$  

(23.14)

All the quantitative estimates in this section apply only in the limit of small $\theta_{\text{rms}}^\text{plane}$, and in the absence of large-angle scatters. The random variables $s$, $\psi$, $y$, and $\theta$ in a given plane are distributed in a correlated fashion (see Sec. 27.1 of this Review for the definition of the correlation coefficient). Obviously, $y \approx z\psi$. In addition, $y$ and $\theta$ have the correlation coefficient $\rho_{yz} = \sqrt{3}/2 \approx 0.87$. For Monte Carlo generation of a joint $(y_{\text{plane}}, \theta_{\text{plane}})$ distribution, or for other calculations, it may be most convenient to work with independent Gaussian random variables $(x_1, x_2)$ with mean zero and variance one, and then set

$$y_{\text{plane}} = x_1 \theta_0(1 - \rho_{yz}^2)/\sqrt{3} + x_2 \rho_{yz} \theta_0 \theta_0/\sqrt{3} = x_1 \theta_0/\sqrt{2} + x_2 \theta_0/2;$$

(23.15)

$$\theta_{\text{plane}} = x_2 \theta_0.$$  

(23.16)

Note that the second term for $y_{\text{plane}}$ equals $x \theta_0/2$ and represents the displacement that would have occurred had the deflection $\theta_{\text{plane}}$ all occurred at the single point $x/2$.

For heavy ions the multiple Coulomb scattering has been measured and compared with various theoretical distributions [33].

23.4. Photon and electron interactions in matter

23.4.1. Radiation length: High-energy electrons predominantly lose energy in matter by bremsstrahlung, and high-energy photons by $e^+ e^-$ pair production. The characteristic amount of matter traversed for these related interactions is called the radiation length $X_0$, usually measured in g cm$^{-2}$. It is the mean distance over which a high-energy electron loses all but $1/e$ of its energy by bremsstrahlung, and the $e$-folding distance for pair production by a high-energy photon is $4X_0$. It is also the appropriate scale length for describing high-energy electromagnetic cascades. $X_0$ has been calculated and tabulated by Y.S. Tsai [34]:

$$\frac{1}{X_0} = 4\pi r_e^2 N_A \left\{ Z^2 |L_{\text{rad}} - f(Z)| + Z L'_{\text{rad}} \right\}.$$

(23.17)

For $A = 1$ g mol$^{-1}$, $4\pi r_e^2 N_A /A = (716.408$ g cm$^{-2})^{-1}$. $L_{\text{rad}}$ and $L'_{\text{rad}}$ are given in Table 23.2. The function $f(Z)$ is an infinite sum, but for elements up to uranium can be represented by 4-place accuracy by

$$f(Z) = a^2 (1 + a^2)^{-1} + 0.20206 - 0.0360 a^2 + 0.0083 a^4 - 0.002 a^6,$$

(23.18)

where $a = aZ$ [35].

Although it is easy to use Eq. (23.17) to calculate $X_0$, the functional dependence on $Z$ is somewhat hidden. Dahl provides a compact fit to the data [36]:

$$X_0 = \frac{716.4 \text{g cm}^{-2}}{Z(Z + 1) \ln(287/\sqrt{Z})}$$

(23.19)
Table 23.2: Tsai’s $L_{\text{rad}}$ and $L'_{\text{rad}}$, for use in calculating the radiation length in an element using Eq. (23.17).

Results obtained with this formula agree with Tsai’s values to better than 2.5% for all elements except helium, where the result is about 5% low.

The radiation length in a mixture or compound may be approximated by

$$\frac{1}{X_0} = \sum w_j/X_j$$  \hspace{1cm} (23.20)

where $w_j$ and $X_j$ are the fraction by weight and the radiation length for the $j$th element.

---

**23. Passage of particles through matter**

---

**Figure 23.7:** Fractional energy loss per radiation length in lead as a function of electron or positron energy. Electron (positron) scattering is considered as ionization when the energy loss per collision is below 0.255 MeV, and as Möller (Bhabha) scattering when it is above. Adapted from Fig. 3.2 from Messel and Crawford, Electron-Photon Shower Distribution Function Tables for Lead, Copper, and Air Absorbers, Pergamon Press, 1970. Messel and Crawford use $X_0$(Pb) = 5.82 g/cm$^2$, but we have modified the figures to reflect the value given in the Table of Atomic and Nuclear Properties of Materials ($X_0$(Pb) = 6.37 g/cm$^2$).

**Figure 23.8:** Two definitions of the critical energy $E_c$.

Results obtained with this formula agree with Tsai’s values to better than 2.5% for all elements except helium, where the result is about 5% low.

The radiation length in a mixture or compound may be approximated by

$$\frac{1}{X_0} = \sum w_j/X_j$$  \hspace{1cm} (23.20)

where $w_j$ and $X_j$ are the fraction by weight and the radiation length for the $j$th element.

---

**Figure 23.9:** (a) The normalized bremsstrahlung cross section $k d\sigma_{LPM}/dk$ in lead versus the fractional photon energy $y = k/E$. The vertical axis has units of photons per radiation length. (b) The normalized pair production cross section $d\sigma_{LPM}/dy$, versus fractional electron energy $x = E/k$.

---

**23.4.2. Energy loss by electrons:** At low energies electrons and positrons primarily lose energy by ionization, although other processes (Möller scattering, Bhabha scattering, $e^+$ annihilation) contribute, as shown in Fig. 23.7. While ionization loss rates rise logarithmically with energy, bremsstrahlung losses rise nearly linearly (fractional loss is nearly independent of energy), and dominates above a few tens of MeV in most materials.

Ionization loss by electrons and positrons differs from loss by heavy particles because of the kinematics, spin, and the identity of the incident electron with the electrons which it ionizes. Complete discussions and tables can be found in Refs. 7, 8, and 22.

At very high energies and except at the high-energy tip of the bremsstrahlung spectrum, the cross section can be approximated in the “complete screening case” as [34]

$$\frac{d\sigma}{dk} = \frac{(1/k)4\pi r_e^2\left\{\left(\frac{1}{3} - \frac{3}{2}y + y^2\right)Z^2(L_{\text{rad}} - f(Z)) + Z L'_{\text{rad}}\right\}}{y(1-y)(Z^2 + Z)}.$$  \hspace{1cm} (23.21)

where $y = k/E$ is the fraction of the electron’s energy transferred to the radiated photon. At small $y$ (the “infrared limit”) the term on the second line can reach 2.5%. If it is ignored and the first line simplified with the definition of $X_0$ given in Eq. (23.17), we have

$$\frac{d\sigma}{dk} = \frac{A}{X_0N_Ak}\left\{\frac{1}{3} - \frac{3}{2}y + y^2\right\}.$$  \hspace{1cm} (23.22)

This cross section (times $k$) is shown by the top curve in Fig. 23.9(a).

This formula is accurate except in near 1, where screening may become incomplete, and near $y = 0$, where the infrared divergence is removed by the interference of bremsstrahlung amplitudes from nearby scattering centers (the LPM effect) [37,38] and dielectric suppression [39,40]. These and other suppression effects in bulk media are discussed in Sec. 23.4.5.

With decreasing energy ($E \lesssim 10$ GeV) the high-$y$ cross section drops and the curves become rounded as $y \to 1$. Curves of this familiar
shape can be seen in Rossi [4] (Figs. 2.11.2,3); see also the review by Koch & Motz [41].

Except at these extremes, and still in the complete-screening approximation, the the number of photons with energies between $k_{\text{max}}$ and $k_{\text{min}}$ emitted by an electron travelling a distance $d \ll X_0$ is

$$N_{\gamma} = \frac{d}{X_0} \left( \frac{4}{3} \ln \left( \frac{k_{\text{max}}}{k_{\text{min}}} \right) - \frac{4(k_{\text{max}} - k_{\text{min}})}{3E} + \frac{(k_{\text{max}} - k_{\text{min}})^2}{2E^2} \right).$$

(23.23)

### 23.4.3. Critical energy

An electron loses energy by bremsstrahlung at a rate nearly proportional to its energy, while the ionization loss rate varies only logarithmically with the electron energy. The critical energy $E_c$ is sometimes defined as the energy at which the two loss rates are equal [42]. Berger and Seltzer [42] also give the approximation $E_c = (800 \text{ MeV})/(Z + 1.2)$. This formula has been widely quoted, and has been given in previous editions of this Review [24]. Among alternate definitions is that of Rossi [4], who defines the critical energy as the energy at which the ionization loss per radiation length is equal to the electron energy. Equivalently, it is the same as the first definition with the approximation $\left| dE/dx \right|_{\text{brems}} \approx E/X_0$. This form has been found to describe more accurately transverse electromagnetic shower development (see below). These definitions are illustrated in the case of copper in Fig. 23.8.

The accuracy of approximate forms for $E_c$ has been limited by the failure to distinguish between gases and solid or liquids, where there is a substantial difference in ionization at the relevant energy because of the density effect. We distinguish these two cases in Fig. 23.10. Fits were also made with functions of the form $a/(Z + b)^\alpha$, but $\alpha$ was found to be essentially unity. Since $E_c$ also depends on $A$, $I$, and other factors, such forms are at best approximate.

### 23.4.4. Energy loss by photons

Contributions to the photon cross section in a light element (carbon) and a heavy element (lead) are shown in Fig. 23.11. At low energies it is seen that the photoelectric effect dominates, although Compton scattering, Rayleigh scattering, and photonuclear absorption also contribute. The photoelectric cross section is characterized by discontinuities (absorption edges) as thresholds for photoionization of various atomic levels are reached. Photon attenuation lengths for a variety of elements are shown in Fig. 23.12, and data for $30 \text{ eV} < k < 100 \text{ GeV}$ for all elements is available from the web pages given in the caption. Here $k$ is the photon energy.

The increasing domination of pair production as the energy increases is shown in Fig. 23.13. Using approximations similar to those used to obtain Eq. (23.22), Tsaï’s formula for the differential cross section [34] reduces to

$$\frac{d\sigma}{dE} = \frac{A}{X_0 N_A} \left[ 1 - \frac{4x(1-x)}{3(1-x)} \right].$$

(23.24)
The photon mass attenuation length (or mean free path) is also pointed out that energy transport approach [37,38].

average multiple scattering, or more rigorously using a quantum Migdal" (LPM) effect may be made semi-classically based on the relativistic electron and the photon "split apart." The interference language, the formation length is the distance over which the highly symmetric between $x$ and $1 - x$, as can be seen by the solid curve in Fig. 23.9(b). See the review by Motz, Olsen, & Koch for a more detailed treatment [43].

Equation Eq. (23.25) is accurate to within a few percent down to energies as low as 1 GeV, particularly for high-Z materials.

**23.4.5. Bremsstrahlung and pair production at very high energies:** At ultrahigh energies, Eqns. 23.21–23.25 will fail because of quantum mechanical interference between amplitudes from different scattering centers. Since the longitudinal momentum transfer to a given center is small ($\propto k/E^2$, in the case of bremsstrahlung), the interaction is spread over a comparatively long distance called the formation length ($\propto E^2/k$) via the uncertainty principle. In alternate language, the formation length is the distance over which the highly relativistic electron and the photon "split apart." The interference is usually destructive. Calculations of the "Landau-Pomeranchuk-Migdal" (LPM) effect may be made semi-classically based on the average multiple scattering, or more rigorously using a quantum transport approach [37,38].

In amorphous media, bremsstrahlung is suppressed if the photon energy $k$ is less than $E^2/E_{LPM}$ [38], where

$$E_{LPM} = \frac{m_e c^2 \rho X_0}{4\pi \hbar c} = (7.7 \text{ TeV/cm}) \times \rho X_0.$$  

* This definition differs from that of Ref. 44 by a factor of two. It is also pointed out that $E_{LPM}$ scales as the 4th power of the mass of the incident particle, so that $E_{LPM} = (1.4 \times 10^{10} \text{ TeV/cm}) \times \rho X_0$ for a muon.

Since physical distances are involved, $\rho X_0$, in cm, appears. The energy-weighted bremsstrahlung spectrum for lead, $k d\sigma_{LPM}/dk$, is shown in Fig. 23.9(a). With appropriate scaling by $\rho X_0$, other materials behave similarly.

For photons, pair production is reduced for $E(k - E) > k E_{LPM}$. The pair-production cross sections for different photon energies are shown in Fig. 23.9(b).
If \( k \ll E \), several additional mechanisms can also produce suppression. When the formation length is long, even weak factors can perturb the interaction. For example, the emitted photon can coherently forward scatter off the electrons in the media. Because of this, for \( k < \omega_{\nu} E/m_e \sim 10^{-3} \), bremsstrahlung is suppressed by a factor \((ke_{\nu}/\omega_{\nu} E)^3\) \([40]\). Magnetic fields can also suppress bremsstrahlung.

In crystalline media, the situation is more complicated, with coherent enhancement or suppression possible. The cross section depends on the electron and photon energies and the angles between the particle direction and the crystalline axes \([38]\).

### 23.5. Electromagnetic cascades

When a high-energy electron or photon is incident on a thick absorber, it initiates an electromagnetic cascade as pair production and bremsstrahlung generate more electrons and photons with lower energy. The longitudinal development is governed by the high-energy part of the cascade, and therefore scales as the radiation length in the material. Electron energies eventually fall below the critical energy, and then dissipate their energy by ionization and excitation rather than by the generation of more shower particles. In describing shower behavior, it is therefore convenient to introduce the scale variables

\[
t = x/X_0, \quad y = E/E_c,
\]

so that distance is measured in units of radiation length and energy in units of critical energy.

Longitudinal profiles for an EGS4 \([23]\) simulation of a 30 GeV electron-induced cascade in iron are shown in Fig. 23.14. The number of particles crossing a plane (very close to Rossi’s II function \([4]\)) is sensitive to the cutoff energy, here chosen as a total energy of 1.5 MeV for both electrons and photons. The electron number falls off more quickly than energy deposition. This is because, with increasing depth, a larger fraction of the cascade energy is carried by photons. Exactly what a calorimeter measures depends on the device, but it is not likely to be exactly any of the profiles shown. In gas counters it may be very close to the electron number, but in glass Čerenkov detectors and other devices with “thick” sensitive regions it is closer to the energy deposition (total track length). In such detectors the signal is proportional to the “detectable” track length \(T_d\), which is in general less than the total track length \(T\). Practical devices are sensitive to electrons with energy above some detection threshold \(E_d\), and \(T_d = T F(E_d/E_c)\). An analytic form for \(F(E_d/E_c)\) obtained by Rossi \([4]\) is given by Fabjan \([45]\); see also Amaldi \([46]\).

The mean longitudinal profile of the energy deposition in an electromagnetic cascade is reasonably well described by a gamma distribution \([47]\):

\[
\frac{dE}{dt} = E_0 b \left(\frac{E}{E_0}\right)^{a-1} e^{-bt} \frac{\Gamma(a)}{\Gamma(a-1)}
\]

The maximum \(t_{\text{max}}\) occurs at \((a - 1)/b\). We have made fits to shower profiles in elements ranging from carbon to uranium, at energies from 1 GeV to 100 GeV. The energy deposition profiles are well described by Eq. (23.28) with

\[
t_{\text{max}} = \frac{(a - 1)}{b} = 1.0 \times (\ln y + C_j), \quad j = e, \gamma,
\]

where \(C_e = -0.5\) for electron-induced cascades and \(C_\gamma = +0.5\) for photon-induced cascades. To use Eq. (23.28), one finds \((a - 1)/b\) from Eq. (23.29) and Eq. (23.27), then finds either by assuming \(b \approx 0.5\) or by finding a more accurate value from Fig. 23.15. The results are very similar for the electron number profiles, but there is some dependence on the atomic number of the medium. A similar form for the electron number maximum was obtained by Rossi in the context of his “Approximation B,” \([4]\) (see Fabjan’s review in Ref. 45), but with \(C_e = -1.0\) and \(C_\gamma = -0.5\); we regard this as superseded by the EGS4 result.

The “shower length” \(X_s = X_0/b\) is less conveniently parameterized, since \(b\) depends upon both \(Z\) and incident energy, as shown in Fig. 23.15. As a corollary of this \(Z\) dependence, the number of electrons crossing a plane near shower maximum is underestimated using Rossi’s approximation for carbon and seriously overestimated for uranium. Essentially the same \(b\) values are obtained for incident electrons and photons. For many purposes it is sufficient to take \(b \approx 0.5\).

The gamma distribution is very flat near the origin, while the EGS4 cascade (or a real cascade) increases more rapidly. As a result Eq. (23.28) fails badly for about the first two radiation lengths; it was necessary to exclude this region in making fits.

Because fluctuations are important, Eq. (23.28) should be used only in applications where average behavior is adequate. Grindhammer et al. have developed fast simulation algorithms in which the variance and correlation of \(a\) and \(b\) are obtained by fitting Eq. (23.28) to individually simulated cascades, then generating profiles for cascades using \(a\) and \(b\) chosen from the correlated distributions \([48]\).

The transverse development of electromagnetic showers in different materials scales fairly accurately with the Molière radius \(R_M\), given by \([49, 50]\)

\[
R_M = X_0 E_0/E_c,
\]

where \(E_0 \approx 21 \text{ MeV}\) (see Table 23.1), and the Rossi definition of \(E_c\) is used.
In a material containing a weight fraction $w_j$ of the element with critical energy $E_{c_j}$ and radiation length $X_j$, the Molière radius is given by

$$R_M = \frac{1}{e_0 \sum w_j E_{c_j}}.$$  \hspace{1cm} (23.31)

Measurements of the lateral distribution in electromagnetic cascades are shown in Refs. 49 and 50. On the average, only 10% of the energy lies outside the cylinder with radius $R_M$. About 99% is contained inside of 3.5$R_M$, but at this radius and beyond composition effects become important and the scaling with $R_M$ fails. The distributions are characterized by a narrow core, and broaden as the shower develops. They are often represented as the sum of two Gaussians, and Grindhammer [48] describes them with the function

$$f(r) = \frac{2r R^2}{(r^2 + R^2)^2},$$  \hspace{1cm} (23.32)

where $R$ is a phenomenological function of $r/X_0$ and $\ln E$.

At high enough energies, the LPM effect (Sec. 23.4.5) reduces the cross sections for bremsstrahlung and pair production, and hence can cause significant elongation of electromagnetic cascades [38].

### 23.6. Muon energy loss at high energy

At sufficiently high energies, radiative processes become more important than ionization for all charged particles. For muons and pions in materials such as iron, this “critical energy” occurs at several hundred GeV. Radiative effects dominate the energy loss of energetic muons found in cosmic rays or produced at the newest accelerators. These processes are characterized by small cross sections, high spectra, large energy fluctuations, and the associated generation of electromagnetic cascades and (in the case of photonuclear interactions) hadron showers [51-59]. As a consequence, at these energies the treatment of energy loss as a uniform and continuous process is for many purposes inadequate.

It is convenient to write the average rate of muon energy loss as

$$-dE/dx = a(E) + b(E).$$  \hspace{1cm} (23.33)

Here $a(E)$ is the ionization energy loss given by Eq. (23.1), and $b(E)$ is the sum of $e^+e^-$ pair production, bremsstrahlung, and photonuclear contributions. To the approximation that these slowly-varying functions are constant, the mean range $x_0$ of a muon with initial energy $E_0$ is given by

$$x_0 \approx (1/b) \ln(1 + E_0/E_{\mu c}),$$  \hspace{1cm} (23.34)

where $E_{\mu c} = a/b$. Figure 23.16 shows contributions to $b(E)$ for iron. Since $a(E) \approx 0.002$ GeV$^{-1}$ cm$^2$, $b(E)$ dominates the energy loss above several hundred GeV, where $b(E)$ is nearly constant. The rate of energy loss for muons in hydrogen, uranium, and iron is shown in Fig. 23.17 [61].

The “muon critical energy” $E_{\mu c}$ can be defined more exactly as the energy at which radiative and ionization losses are equal, and can be found by solving $E_{\mu c} = a(E_{\mu c})/b(E_{\mu c})$. This definition corresponds to the solid-line intersection in Fig. 23.8, and is different from the Rossi definition we used for electrons. It serves the same function: below $E_{\mu c}$ ionization losses dominate, and above $E_{\mu c}$ dominate. The dependence of $E_{\mu c}$ on atomic number $Z$ is shown in Fig. 23.18.

The radiative cross sections are expressed as functions of the fractional energy loss $\nu$. The bremsstrahlung cross section goes roughly as $1/\nu$ over most of the range, while for the pair production case the distribution goes as $\nu^{-3}$ to $\nu^{-2}$ (see Ref. 62). “Hard” losses are therefore more probable in bremsstrahlung, and in fact energy losses due to pair production may very nearly be treated as continuous. The calculated momentum distribution of an incident 1 TeV/c muon beam after it crosses 3 m of iron is shown in Fig. 23.19. The most probable loss is 9 GeV, or 3.8 MeV g$^{-1}$ cm$^2$. The full width at half maximum is 7 GeV/c, or 0.7%. The radiative tail is almost entirely due to bremsstrahlung; this includes most of the 10% that lost more than 2.8% of their energy. Most of the 3.3% that lost more than 10% of

---

**Figure 23.16:** Contributions to the fractional energy loss by muons in iron due to $e^+e^-$ pair production, bremsstrahlung, and photonuclear interactions, as obtained from Lohmann et al. [61].

**Figure 23.17:** The average energy loss of a muon in hydrogen, iron, and uranium as a function of muon energy. Contributions to $dE/dx$ in iron from ionization and the processes shown in Fig. 23.16 are also shown.

**Figure 23.18:** Muon critical energy for the chemical elements, defined as the energy at which radiative and ionization energy losses are equal [1]. The equality comes at a higher energy for gases than for solids or liquids with the same atomic number because of a smaller density effect reduction of the ionization losses. The fits shown in the figure exclude hydrogen. All alkali metals fall 3-4% above the fitted function, while most other solids are within 2% of the function. Among the gases the worst fit is for neon (1.5% high).
their incident energy experienced photonuclear interactions, which are concentrated in rare, relatively hard collisions. The latter can exceed nominal detector resolution [63], necessitating the reconstruction of lost energy. Electromagnetic and hadronic cascades in detector materials can obscure muon tracks in detector planes and reduce tracking efficiency [64].

Figure 23.19: The momentum distribution of 1 TeV/c muons after traversing 3 m of iron, as obtained with Van Ginniken’s TRAMU muon transport code [62].

23.7. Čerenkov and transition radiation \[10, 65, 66\]

A charged particle radiates if its velocity is greater than the local phase velocity of light (Čerenkov radiation) or if it crosses suddenly from one medium to another with different optical properties (transition radiation). Neither process is important for energy loss, but both are used in high-energy physics detectors.

Čerenkov Radiation. The half-angle \( \theta_c \) of the Čerenkov cone for a particle with velocity \( \beta c \) in a medium with index of refraction \( n \) is
\[
\theta_c = \arccos\left(\frac{1}{n}\right) = \sqrt{2\left(1 - \frac{1}{n^2}\right)} \quad \text{for small } \theta_c, \text{ e.g. in gases.} \tag{23.35}
\]

The threshold velocity \( \beta_c \) is \( n = 1 \), and \( \gamma_c = 1/(1 - \beta_c^2)^{1/2} \). Therefore, \( \beta_c^2 \gamma_c = 1/(20 + \delta^2)^{1/2} \), where \( \delta = n - 1 \). Values of \( \delta \) for various commonly used gases are given as a function of pressure and wavelength in Ref. 67. For values at atmospheric pressure, see Table 6.1. Data for other commonly used materials are given in Ref. 68.

The number of photons produced per unit path length of a particle with charge \( e \) and per unit energy interval of the photons is
\[
\frac{d^2 N}{dE d \omega} = \frac{\alpha e^2}{c \beta \sin^2 \theta_c} = \frac{\alpha e^2}{c \beta \sin^2 \theta_c(p_e, m_ec^2) \left(1 - \frac{1}{\beta^2\gamma^2(E)}\right)} \approx 370\sin^2 \theta_c(p_e) \text{ eV}^{-1} \text{ cm}^{-1} \tag{23.36}
\]

or, equivalently,
\[
\frac{d^2 N}{dE d \omega} = \frac{2\pi \alpha e^2}{\lambda^2} \left(1 - \frac{1}{\beta^2\gamma^2(E)}\right) \tag{23.37}
\]

The index of refraction is a function of photon energy \( E \), as is the sensitivity of the transducer used to detect the light. For practical use, Eq. (23.36) must be multiplied by the the transducer response function and integrated over the region for which \( \beta \gamma(E) > 1 \). Further details are given in the discussion of Čerenkov detectors in the Detectors section (Sec. 24 of this Review).

Transition Radiation. The energy radiated when a particle with charge \( e \) crosses the boundary between vacuum and a medium with plasma frequency \( \omega_p \) is
\[
I = \frac{\alpha^2 \gamma \hbar \omega_p}{3}, \tag{23.38}
\]

where
\[
\hbar \omega_p = \sqrt{\frac{4\pi N e^2}{m_c^2 c^2}} \tag{23.39}
\]

Here \( N_e \) is the electron density in the medium, \( r_e \) is the classical electron radius, and \( a_\infty \) is the Bohr radius. For styrene and similar materials, \( 4\pi N_e a_\infty^2 \approx 0.8 \), so that \( \hbar \omega_p \approx 20 \text{ eV} \). The typical emission angle is \( 1/\gamma \).

The radiation spectrum is logarithmically divergent at low energies and decreases rapidly for \( \hbar \omega /\hbar \omega_p > 1 \). About half the energy is emitted in the range \( 0.1 < \omega /\hbar \omega < 1 \). For a particle with \( \gamma = 10^8 \), the radiated photons are in the soft x-ray range 2 to 20 keV. The \( \gamma \) dependence of the emitted energy thus comes from the hardening of the spectrum rather than from an increased quantum yield. For a typical radiated photon energy of \( \gamma \hbar \omega_p/4 \), the quantum yield is
\[
N_\gamma \approx \frac{1}{2} \frac{\alpha^2 \gamma^2 \hbar \omega_p}{3} \quad \hbar \omega_p \approx \gamma \hbar \omega_0 \tag{23.40}
\]

within corrections of order \( (\hbar \omega_0/\gamma) \). The number of photons above a fixed energy \( \hbar \omega_0 \ll \gamma \hbar \omega_p \) thus grows as \( \ln \gamma^2 \), but the number above a fixed fraction of \( \gamma \hbar \omega_p \) (as in the example above) is constant. For example, for \( \hbar \omega > \gamma \hbar \omega_p/10 \), \( N_\gamma \approx 2.519 \alpha^2 \gamma^2 /\pi 
 0.59\% \times \gamma \). The yield can be increased by using a stack of plastic foils with gaps between. However, interference can be important, and the soft x rays are readily absorbed in the foils. The first problem can be overcome by choosing thicknesses and spacings large compared to the “formation length” \( D = \gamma c/\omega_p \), which in practical situations is tens of \( \mu \text{m} \). Other practical problems are discussed in Sec. 24.
