

11. THE CKM QUARK-MIXING MATRIX

Written January 2006 by A. Ceccucci (CERN), Z. Ligeti (LBNL), and Y. Sakai (KEK).

11.1. Introduction

The masses and mixings of quarks have a common origin in the Standard Model (SM). They arise from the Yukawa interactions with the Higgs condensate,

$$\mathcal{L}_Y = -Y_{ij}^d \overline{Q_{Li}^I} \phi d_{Rj}^I - Y_{ij}^u \overline{Q_{Li}^I} \epsilon \phi^* u_{Rj}^I + \text{h.c.}, \quad (11.1)$$

where $Y^{u,d}$ are 3×3 complex matrices, ϕ is the Higgs field, i, j are generation labels, and ϵ is the 2×2 antisymmetric tensor. Q_L^I are left handed quark doublets, and d_R^I and u_R^I are right handed down- and up-type quark singlets, respectively, in the weak-eigenstate basis. When ϕ acquires a vacuum expectation value, $\langle \phi \rangle = (0, v/\sqrt{2})$, Eq. (11.1) yields mass terms for the quarks. The physical states are obtained by diagonalizing $Y^{u,d}$ by four unitary matrices, $V_{L,R}^{u,d}$, as $M_{\text{diag}}^f = V_L^f Y^f V_R^{f\dagger} (v/\sqrt{2})$, $f = u, d$. As a result, the charged current W^\pm interactions couple to the physical u_{Lj} and d_{Lk} quarks with couplings given by

$$V_{\text{CKM}} \equiv V_L^u V_L^{d\dagger} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \quad (11.2)$$

This Cabibbo-Kobayashi-Maskawa (CKM) matrix [1,2] is a 3×3 unitary matrix. It can be parameterized by three mixing angles and a CP -violating phase. Of the many possible parameterizations, a standard choice is [3]

$$V = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{pmatrix}, \quad (11.3)$$

where $s_{ij} = \sin \theta_{ij}$, $c_{ij} = \cos \theta_{ij}$, and δ is the KM phase [2] responsible for all CP -violating phenomena in flavor changing processes in the SM. The angles θ_{ij} can be chosen to lie in the first quadrant, so $s_{ij}, c_{ij} \geq 0$.

It is known experimentally that $s_{13} \ll s_{23} \ll s_{12} \ll 1$, and it is convenient to exhibit this hierarchy using the Wolfenstein parameterization. We define [4–6]

$$s_{12} = \lambda = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}}, \quad s_{23} = A\lambda^2 = \lambda \left| \frac{V_{cb}}{V_{us}} \right|, \\ s_{13}e^{i\delta} = V_{ub}^* = A\lambda^3(\bar{\rho} + i\bar{\eta}) = \frac{A\lambda^3(\bar{\rho} + i\bar{\eta})\sqrt{1 - A^2\lambda^4}}{\sqrt{1 - \lambda^2[1 - A^2\lambda^4(\bar{\rho} + i\bar{\eta})]}}. \quad (11.4)$$

These ensure that $\bar{\rho} + i\bar{\eta} = -(V_{ud}V_{ub}^*)/(V_{cd}V_{cb}^*)$ is phase-convention independent and the CKM matrix written in terms of $\lambda, A, \bar{\rho}$ and $\bar{\eta}$ is unitary to all orders in λ . The definitions of $\bar{\rho}, \bar{\eta}$ reproduce all approximate results in the literature. *E.g.*, $\bar{\rho} = \rho(1 - \lambda^2/2 + \dots)$ and we can write V_{CKM} to $\mathcal{O}(\lambda^4)$ either in terms of $\bar{\rho}, \bar{\eta}$ or, traditionally,

$$V = \begin{pmatrix} 1 - \lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1 - \lambda^2/2 & A\lambda^2 \\ A\lambda^3(1 - \rho - i\eta) & -A\lambda^2 & 1 \end{pmatrix} + \mathcal{O}(\lambda^4). \quad (11.5)$$

2 11. CKM quark-mixing matrix

Figure 11.1: Sketch of the unitarity triangle.

The CKM matrix elements are fundamental parameters of the SM, so their precise determination is important. The unitarity of the CKM matrix imposes $\sum_i V_{ij} V_{ik}^* = \delta_{jk}$ and $\sum_j V_{ij} V_{kj}^* = \delta_{ik}$. The six vanishing combinations can be represented as triangles in a complex plane, of which the ones obtained by taking scalar products of neighboring rows or columns are nearly degenerate. The areas of all triangles are the same, half of the Jarlskog invariant, J [7], which is a phase-convention independent measure of CP violation, $\text{Im}[V_{ij} V_{kl} V_{il}^* V_{kj}^*] = J \sum_{m,n} \varepsilon_{ikm} \varepsilon_{jln}$.

The most commonly used unitarity triangle arises from

$$V_{ud} V_{ub}^* + V_{cd} V_{cb}^* + V_{td} V_{tb}^* = 0, \quad (11.6)$$

by dividing each side by the best-known one, $V_{cd} V_{cb}^*$ (see Fig. 1). Its vertices are exactly $(0,0)$, $(1,0)$ and, due to the definition in Eq. (11.4), $(\bar{\rho}, \bar{\eta})$. An important goal of flavor physics is to overconstrain the CKM elements, and many measurements can be conveniently displayed and compared in the $\bar{\rho}, \bar{\eta}$ plane.

Processes dominated by loop contributions in the SM are sensitive to new physics and can be used to extract CKM elements only if the SM is assumed. In Sec. 11.2 and 11.3 we describe such measurements assuming the SM, and discuss implications for new physics in Sec. 11.5.

11.2. Magnitudes of CKM elements

11.2.1. $|V_{ud}|$:

The most precise determination of $|V_{ud}|$ comes from the study of superallowed $0^+ \rightarrow 0^+$ nuclear beta decays, which are pure vector transitions. Taking the average of the nine most precise determinations [8,9] yields [10]

$$|V_{ud}| = 0.97377 \pm 0.00027. \quad (11.7)$$

The error is dominated by theoretical uncertainties stemming from nuclear Coulomb distortions and radiative corrections. A recent measurement of ^{46}V performed using an atomic Penning trap method [9] deviates by 2.7 standard deviations from the average and may indicate a need to remeasure superallowed $0^+ \rightarrow 0^+$ transitions with modern atomic physics techniques. A precise determination of $|V_{ud}|$ is also obtained from the measurement of the neutron lifetime. The theoretical uncertainties are very small but the determination is limited by the knowledge of the ratio of the axial-vector and vector couplings, $g_A = G_A/G_V$ [10]. The PIBETA experiment [11] has improved the measurement of the $\pi^+ \rightarrow \pi^0 e^+ \nu$ branching ratio to 0.6%, and quote $|V_{ud}| = 0.9728 \pm 0.0030$, in agreement with the more precise results listed above. The interest in this measurement is that the determination of $|V_{ud}|$ is very clean theoretically, because it is a pure vector transition and is free from nuclear structure uncertainties.

11.2.2. $|V_{us}|$:

The magnitude of V_{us} has been extracted traditionally from semileptonic kaon decays. Significant progress on the experimental side has taken place during the last two years. After a high statistics measurement of $\mathcal{B}(K^+ \rightarrow \pi^0 e^+ \nu)$ [12], a suite of measurements of neutral kaon branching ratios [13–15], form factors [16], and lifetime [17] followed. An early value of $f_+(0) = 0.961 \pm 0.008$ [18] is still broadly accepted [10,19]. It yields from the kaon semileptonic decay rate

$$|V_{us}| = 0.2257 \pm 0.0021. \quad (11.8)$$

A word of caution is in order, since other calculations of $f_+(0)$ [20,21] differ by as much as 2%, with uncertainties around 1%.

Other determinations of $|V_{us}|$ involve leptonic kaon decays, hyperon decays, and τ decays. The calculation of the ratio of the kaon and pion decay constants enables one to extract $|V_{us}/V_{ud}|$ from $K \rightarrow \mu\nu(\gamma)$ and $\pi \rightarrow \mu\nu(\gamma)$, where (γ) indicates that radiative decays are included [22]. The KLOE measurement of the $K^+ \rightarrow \mu^+ \nu(\gamma)$ branching ratio [23], combined with the unquenched lattice QCD calculation, $f_K/f_\pi = 1.198 \pm 0.003_{-0.005}^{+0.016}$ [24], leads to $|V_{us}| = 0.2245_{-0.0031}^{+0.0012}$, where the accuracy is limited by the knowledge of the ratio of the decay constants. Hereafter, the first error is statistical and the second is systematic, unless mentioned otherwise. The determination from hyperon decays was recently updated [25]. These authors focus on the analysis of the vector form factor, protected from first order $SU(3)$ breaking effects by the Ademollo-Gatto theorem [26], and treat the ratio between the axial and vector form factors g_1/f_1 as experimental input, thus avoiding first order $SU(3)$ breaking effects in the axial-vector contribution. They find $|V_{us}| = 0.2250 \pm 0.0027$, although this does not include an estimate of the theoretical uncertainty due to second order $SU(3)$ breaking, contrary to Eq. (11.8). Concerning hadronic τ decays to strange particles, the latest determinations based on OPAL or ALEPH data also yields consistent results [27] with accuracy around 0.003.

4 11. CKM quark-mixing matrix

11.2.3. $|V_{cd}|$:

The magnitude of V_{cd} can be extracted from semileptonic charm decays if theoretical knowledge of the form factors is available. Recently, the first three-flavor unquenched lattice QCD calculations for $D \rightarrow K\ell\nu$ and $D \rightarrow \pi\ell\nu$ have been published [28]. Using these estimates and the isospin-averaged charm semileptonic width measured by CLEO-c, one obtains $|V_{cd}| = 0.213 \pm 0.008 \pm 0.021$ [29], where the first uncertainty is experimental and the second is from the theoretical error of the form factor.

This determination is not yet as precise as the one based on neutrino and antineutrino interactions. The difference of the ratio of double-muon to single-muon production by neutrino and antineutrino beams is proportional to the charm cross section off valence d -quarks, and therefore to $|V_{cd}|^2$ times the average semileptonic branching ratio of charm mesons, \mathcal{B}_μ . The method was used first by CDHS [30] and then by CCFR [31,32] and CHARM II [33]. Averaging these results is complicated, not only because it requires assumptions about the scale of the QCD corrections, but also because \mathcal{B}_μ is an effective quantity, which depends on the specific neutrino beam characteristics. Given that no new experimental input is available, we quote the average provided in the previous edition of this review, $\mathcal{B}_\mu|V_{cd}|^2 = (0.463 \pm 0.034) \times 10^{-2}$ [3]. Analysis cuts make these experiments insensitive to neutrino energies smaller than 30 GeV. Thus, \mathcal{B}_μ should be computed using only neutrino interactions with visible energy larger than 30 GeV. A recent appraisal [34] based on charm production fractions measured in neutrino interactions [35,36] gives $\mathcal{B}_\mu = 0.088 \pm 0.006$. Data from the CHORUS experiment [37] are now sufficiently precise to extract \mathcal{B}_μ directly, by comparing the number of charm decays with a muon to the total number of charmed hadrons found in the nuclear emulsions. Requiring the visible energy to be larger than 30 GeV, CHORUS finds $\mathcal{B}_\mu = 0.085 \pm 0.009 \pm 0.006$. To extract $|V_{cd}|$, we use the average of these two determinations, $\mathcal{B}_\mu = 0.0873 \pm 0.0052$, and obtain

$$|V_{cd}| = 0.230 \pm 0.011. \quad (11.9)$$

11.2.4. $|V_{cs}|$:

The determination of $|V_{cs}|$ from neutrino and antineutrino scattering suffers from the uncertainty of the s -quark sea content. Measurements sensitive to $|V_{cs}|$ from on-shell W^\pm decays were performed at LEP-2. The branching ratios of the W depend on the six CKM matrix elements involving quarks with masses smaller than M_W . The W branching ratio to each lepton flavor is $1/\mathcal{B}(W \rightarrow \ell\bar{\nu}_\ell) = 3[1 + \sum_{u,c,d,s,b} |V_{ij}|^2 (1 + \alpha_s(m_W)/\pi)]$. The measurement assuming lepton universality, $\mathcal{B}(W \rightarrow \ell\bar{\nu}_\ell) = (10.83 \pm 0.07 \pm 0.07)\%$ [38], implies $\sum_{u,c,d,s,b} |V_{ij}|^2 = 2.002 \pm 0.027$. This is a precise test of unitarity, but only flavor-tagged measurements determine $|V_{cs}|$. DELPHI measured tagged $W^+ \rightarrow c\bar{s}$ decays, obtaining $|V_{cs}| = 0.94_{-0.26}^{+0.32} \pm 0.13$ [39].

The direct determination of $|V_{cs}|$ is possible from semileptonic D or leptonic D_s decays, relying on the calculations of hadronic matrix elements. The measurement in $D_s^+ \rightarrow \ell^+\nu$ requires the lattice QCD calculation of the decay constant, f_{D_s} , while in semileptonic D decays one needs the form factors which depend on the invariant mass of the lepton pair, q^2 . Unquenched lattice QCD calculations have predicted the normalization and the shape

of the form factor in $D \rightarrow K\ell\nu$ and $D \rightarrow \pi\ell\nu$ [28]. Using these theoretical results and the isospin averaged semileptonic widths one obtains [29]

$$|V_{cs}| = 0.957 \pm 0.017 \pm 0.093, \quad (11.10)$$

where the first error is experimental and the second one, which is dominant, is from the theoretical error of the form factor.

11.2.5. $|V_{cb}|$:

This matrix element can be determined from exclusive and inclusive semileptonic decays of B mesons to charm. The inclusive determinations use the semileptonic decay rate measurement together with the leptonic energy and the hadronic invariant-mass spectra. The theoretical foundation of the calculation is the operator product expansion (OPE) [40,41]. It expresses the total rate and moments of differential energy and invariant-mass spectra as expansions in α_s and inverse powers of the heavy quark mass. The dependence on m_b , m_c , and the parameters that occur at subleading order is different for different moments, and a large number of measured moments overconstrains all the parameters and tests the consistency of the determination. The precise extraction of $|V_{cb}|$ requires using a “threshold” quark mass definition [42,43]. Inclusive measurements have been performed using B mesons from Z^0 decays at LEP and at e^+e^- machines operated at the $\Upsilon(4S)$. At LEP the large boost of B mesons from Z^0 allows one to determine the moments throughout phase space, which is not possible otherwise, but the large statistics available at the B factories leads to more precise determinations. An average of the measurements and a compilation of the references are provided by Kowalewski and Mannel [44]: $|V_{cb}| = (41.7 \pm 0.7) \times 10^{-3}$.

Exclusive determinations are based on semileptonic B decays to D and D^* . In the $m_{b,c} \gg \Lambda_{\text{QCD}}$ limit, all form factors are given by a single Isgur-Wise function [45], which depends on the product of the four-velocities, $w = v \cdot v'$, of the initial and final state hadrons. Heavy quark symmetry determines the normalization of the rate at $w = 1$, the maximum momentum transfer to the leptons, and $|V_{cb}|$ is obtained from an extrapolation to $w = 1$. The exclusive determination, $|V_{cb}| = (40.9 \pm 1.8) \times 10^{-3}$ [44], is less precise than the inclusive one, because the theoretical uncertainty in the form factor and the experimental uncertainty in the rate near $w = 1$ are both about 3%. The $|V_{cb}|$ review quotes the average as [44]

$$|V_{cb}| = (41.6 \pm 0.6) \times 10^{-3}. \quad (11.11)$$

11.2.6. $|V_{ub}|$:

The determination of $|V_{ub}|$ from inclusive $B \rightarrow X_u\ell\bar{\nu}$ decay suffers from large $B \rightarrow X_c\ell\bar{\nu}$ backgrounds. In most regions of phase space where the charm background is kinematically forbidden the hadronic physics enters via unknown nonperturbative functions, so-called shape functions. (In contrast, the nonperturbative physics for $|V_{cb}|$ is encoded in a few parameters.) At leading order in Λ_{QCD}/m_b there is only one shape function, which can be extracted from the photon energy spectrum in $B \rightarrow X_s\gamma$ [46,47] and applied to several spectra in $B \rightarrow X_u\ell\bar{\nu}$. The subleading shape functions are modeled

6 11. CKM quark-mixing matrix

in the current calculations. Phase space cuts for which the rate does not depend on the shape function are also possible [48]. The measurements of both hadronic and leptonic system are important for effective choice of phase space. A different approach is to extend the measurements deeper into the $B \rightarrow X_c \ell \bar{\nu}$ region to reduce the theoretical uncertainties. Analyses of the electron-energy endpoint from CLEO [49], BABAR [50] and Belle [51] quote $B \rightarrow X_u e \bar{\nu}$ partial rates for $|\vec{p}_e| \geq 2.0 \text{ GeV}$ and 1.9 GeV , which are well below the charm endpoint. The large and pure $B-\bar{B}$ samples at the B factories permit the selection of $B \rightarrow X_u \ell \bar{\nu}$ decays in events where the other B is fully reconstructed [52]. With this full-reconstruction tag method the four-momenta of both the leptonic and the hadronic systems can be measured. It also gives access to a wider kinematic region due to improved signal purity.

To extract $|V_{ub}|$ from an exclusive channel, the form factors have to be known. Experimentally, better signal-to-background ratios are offset by smaller yields. The $B \rightarrow \pi \ell \bar{\nu}$ branching ratio is now known to 8%. The first unquenched lattice QCD calculations of the $B \rightarrow \pi \ell \bar{\nu}$ form factor for $q^2 > 16 \text{ GeV}^2$ appeared recently [53,54]. Light-cone QCD sum rules are applicable for $q^2 < 14 \text{ GeV}^2$ [55] and yield somewhat smaller $|V_{ub}|$, $(3.3^{+0.6}_{-0.4}) \times 10^{-3}$. The theoretical uncertainties in extracting $|V_{ub}|$ from inclusive and exclusive decays are different. A combination of the determinations is quoted by the V_{cb} and V_{ub} minireview as [44],

$$|V_{ub}| = (4.31 \pm 0.30) \times 10^{-3}, \quad (11.12)$$

which is dominated by the inclusive measurement. In the previous edition of the RPP [56] the average was reported as $|V_{ub}| = (3.67 \pm 0.47) \times 10^{-3}$, with an uncertainty around 13%. The new average is 17% larger, somewhat above the range favored by the measurement of $\sin 2\beta$ discussed below. Given the rapid theoretical and experimental progress, it will be interesting how the determination of $|V_{ub}|$ develops.

11.2.7. $|V_{td}|$ and $|V_{ts}|$:

The CKM elements $|V_{td}|$ and $|V_{ts}|$ cannot be measured from tree-level decays of the top quark, so one has to rely on determinations from $B-\bar{B}$ oscillations mediated by box diagrams or loop-mediated rare K and B decays. Theoretical uncertainties in hadronic effects limit the accuracy of the current determinations. These can be reduced by taking ratios of processes that are equal in the flavor $SU(3)$ limit to determine $|V_{td}/V_{ts}|$.

The mass difference of the two neutral B meson mass eigenstates is very well measured, $\Delta m_d = 0.507 \pm 0.004 \text{ ps}^{-1}$ [57]. It is dominated by box diagrams with top quarks. Using the unquenched lattice QCD calculation of the B_d decay constant and bag parameter, $f_{B_d} \sqrt{\widehat{B}_{B_d}} = 244 \pm 11 \pm 24 \text{ MeV}$ [58,59], and assuming $|V_{tb}| = 1$, one finds [60]

$$|V_{td}| = (7.4 \pm 0.8) \times 10^{-3}, \quad (11.13)$$

where the uncertainty is dominated by that of $f_{B_d} \sqrt{\widehat{B}_{B_d}}$. Several uncertainties are reduced in the lattice calculation of the ratio $\xi = (f_{B_s} \sqrt{\widehat{B}_{B_s}})/(f_{B_d} \sqrt{\widehat{B}_{B_d}}) =$

$1.21 \pm 0.04_{-0.01}^{+0.04}$, and therefore the constraint on $|V_{td}/V_{ts}|$ from Δm_d and Δm_s would be more reliable theoretically. So far only a lower bound is available, $\Delta m_s > 16.6 \text{ ps}^{-1}$ at 95% CL [57], which implies $|V_{td}/V_{ts}| < 0.22$ at 95% CL. After completion of this review, new $D\bar{O}$ and CDF analyses appeared, obtaining $17 \text{ ps}^{-1} < \Delta m_s < 21 \text{ ps}^{-1}$ at 90% CL [61], and $\Delta m_s = (17.31_{-0.18}^{+0.33} \pm 0.07) \text{ ps}^{-1}$ [62], respectively. These provide a new theoretically clean and significantly improved constraint, $|V_{td}/V_{ts}| = 0.208_{+0.006}^{+0.008}$ [62].

The inclusive rate $\mathcal{B}(B \rightarrow X_s \gamma) = (3.55 \pm 0.26) \times 10^{-4}$ for $E_\gamma > 1.6 \text{ GeV}$ [57] is sensitive to $V_{tb}V_{ts}^*$ via t -quark penguins. However, a large contribution to the rate comes from the $b \rightarrow c\bar{c}s$ four-quark operators mixing into the electromagnetic dipole operator. Since any CKM determination from loop processes necessarily assumes the SM, using $V_{cb}V_{cs}^* \approx -V_{tb}V_{ts}^*$, we obtain $|V_{ts}| = (40.6 \pm 2.7) \times 10^{-3}$ [63].

The corresponding exclusive decays suffer from larger theoretical uncertainties due to unknown hadronic form factors, although the experimental accuracy is better. Recently, Belle observed exclusive $B \rightarrow (\rho/\omega)\gamma$ signals [64] in $b \rightarrow d\gamma$ decays. The theoretically cleanest determination of $|V_{td}/V_{ts}|$ in exclusive radiative B decays will come from $\mathcal{B}(B^0 \rightarrow \rho^0\gamma)/\mathcal{B}(B^0 \rightarrow K^{*0}\gamma)$, because the poorly known spectator interaction contribution is expected to be smaller in this ratio than that in charged B decay (W -exchange vs. weak annihilation). For now, we average the neutral and charged modes, assuming isospin symmetry, which gives $\mathcal{B}(B \rightarrow \rho\gamma)/\mathcal{B}(B \rightarrow K^*\gamma) = 0.017 \pm 0.006$ [57]. This ratio is $|V_{td}/V_{ts}|^2/\xi_\gamma^2$, where ξ_γ contains the hadronic physics, and is unity in the $SU(3)$ limit. Using $\xi_\gamma = 1.2 \pm 0.2$ [65], implies $|V_{td}/V_{ts}| = 0.16 \pm 0.04$, where we combined the experimental and theoretical errors in quadrature.

A theoretically clean determination of $|V_{td}V_{ts}^*|$ is possible from $K^+ \rightarrow \pi^+\nu\bar{\nu}$ decay [66]. Experimentally, only three events have been observed [67], and the rate is consistent with the SM with large uncertainties. Much more data are needed for a precision measurement.

11.2.8. $|V_{tb}|$:

The direct determination of $|V_{tb}|$ from top decays uses the ratio of branching fractions $R = \mathcal{B}(t \rightarrow Wb)/\mathcal{B}(t \rightarrow Wq) = |V_{tb}|^2/(\sum_q |V_{tq}|^2) = |V_{tb}|^2$, where $q = b, s, d$. The CDF and $D\bar{O}$ measurements performed on data collected during Run II of the Tevatron give $R = 1.12_{-0.23}^{+0.27}$ [68] and $R = 1.03_{-0.17}^{+0.19}$ [69], respectively. Both measurements result in the 95% CL lower limit

$$|V_{tb}| > 0.78. \quad (11.14)$$

An attempt at constraining $|V_{tb}|$ from the precision electroweak data was made in [70]. The result, mostly driven by the top-loop contributions to $\Gamma(Z \rightarrow b\bar{b})$, gives $|V_{tb}| = 0.77_{-0.24}^{+0.18}$.

8 11. CKM quark-mixing matrix

11.3. Phases of CKM elements

As can be seen from Fig. 11.1, the angles of the unitarity triangle are

$$\begin{aligned}\beta &= \phi_1 = \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right), \\ \alpha &= \phi_2 = \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right), \\ \gamma &= \phi_3 = \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right).\end{aligned}\tag{11.15}$$

Since CP violation involves phases of CKM elements, many measurements of CP -violating observables can be used to constraint these angles and the $\bar{\rho}, \bar{\eta}$ parameters.

11.3.1. ϵ and ϵ' :

The measurement of CP violation in $K^0-\bar{K}^0$ mixing, $|\epsilon| = (2.233 \pm 0.015) \times 10^{-3}$ [71], provides important information about the CKM matrix. In the SM [72]

$$\begin{aligned}|\epsilon| &= \frac{G_F^2 f_K^2 m_K m_W^2}{12\sqrt{2}\pi^2 \Delta m_K} \widehat{B}_K \left\{ \eta_c S(x_c) \text{Im}[(V_{cs}V_{cd}^*)^2] \right. \\ &\left. + \eta_t S(x_t) \text{Im}[(V_{ts}V_{td}^*)^2] + 2\eta_{ct} S(x_c, x_t) \text{Im}(V_{cs}V_{cd}^*V_{ts}V_{td}^*) \right\},\end{aligned}\tag{11.16}$$

where S is an Inami-Lim function [73], $x_q = m_q^2/m_W^2$, and η_i are perturbative QCD corrections. The constraint from ϵ in the $\bar{\rho}, \bar{\eta}$ plane are bounded by hyperbolas approximately. The dominant uncertainties are due to the bag parameter, for which we use $\widehat{B}_K = 0.79 \pm 0.04 \pm 0.09$ from lattice QCD [74], and the parametric uncertainty proportional to $\sigma(A^4)$ [*i.e.*, $\sigma(|V_{cb}|^4)$].

The measurement of ϵ' provides a qualitative test of the CKM mechanism because its nonzero experimental average, $\text{Re}(\epsilon'/\epsilon) = (1.67 \pm 0.23) \times 10^{-3}$ [71], demonstrated the existence of direct CP violation, a prediction of the KM ansatz. While $\text{Re}(\epsilon'/\epsilon) \propto \text{Im}(V_{td}V_{ts}^*)$, this quantity cannot easily be used to extract CKM parameters, because the electromagnetic penguin contributions tend to cancel the gluonic penguins for large m_t [75], thereby significantly increasing the hadronic uncertainties. Most estimates [76,77] are in agreement with the observed value, indicating a positive value for $\bar{\eta}$. Progress in lattice QCD, in particular finite-volume calculations [78,79], may eventually provide a determination of the $K \rightarrow \pi\pi$ matrix elements.

11.3.2. β / ϕ_1 :

11.3.2.1. Charmonium modes:

CP violation measurements in B meson decays provide direct information on the angles of the unitarity triangle, shown in Fig. 11.1. These overconstraining measurements serve to improve the determination of the CKM elements or to reveal effects beyond the SM.

The time-dependent CP asymmetry of neutral B decays to a final state f common to B^0 and \bar{B}^0 is given by [80,81]

$$\mathcal{A}_f = \frac{\Gamma(\bar{B}^0(t) \rightarrow f) - \Gamma(B^0(t) \rightarrow f)}{\Gamma(\bar{B}^0(t) \rightarrow f) + \Gamma(B^0(t) \rightarrow f)} = S_f \sin(\Delta m t) - C_f \cos(\Delta m t), \quad (11.17)$$

where

$$S_f = \frac{2 \operatorname{Im} \lambda_f}{1 + |\lambda_f|^2}, \quad C_f = \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2}, \quad \lambda_f = \frac{q \bar{A}_f}{p A_f}. \quad (11.18)$$

Here q/p describes B^0 - \bar{B}^0 mixing and, to a good approximation in the SM, $q/p = V_{tb}^* V_{td} / V_{tb} V_{td}^* = e^{-2i\beta + \mathcal{O}(\lambda^4)}$ in the usual phase convention. A_f (\bar{A}_f) is the amplitude of $B^0 \rightarrow f$ ($\bar{B}^0 \rightarrow f$) decay. If f is a CP eigenstate and amplitudes with one CKM phase dominate a decay, then $|A_f| = |\bar{A}_f|$, $C_f = 0$ and $S_f = \sin(\arg \lambda_f) = \eta_f \sin 2\phi$, where η_f is the CP eigenvalue of f and 2ϕ is the phase difference between the $B^0 \rightarrow f$ and $B^0 \rightarrow \bar{B}^0 \rightarrow f$ decay paths. A contribution of another amplitude to the decay with a different CKM phase makes the value of S_f sensitive to relative strong interaction phases between the decay amplitudes (it also makes $C_f \neq 0$ possible).

The $b \rightarrow c\bar{c}s$ decays to CP eigenstates ($B^0 \rightarrow$ charmonium $K_{S,L}^0$) are the theoretically cleanest examples, measuring $S_f = -\eta_f \sin 2\beta$. The $b \rightarrow sq\bar{q}$ penguin amplitudes have dominantly the same weak phase as the $b \rightarrow c\bar{c}s$ tree amplitude. Since only λ^2 -suppressed penguin amplitudes introduce a new CP -violating phase, amplitudes with a single weak phase dominate these decays, and we expect $||\bar{A}/A| - 1| < 0.01$. The e^+e^- asymmetric-energy B -factory experiments BABAR [82] and Belle [83] provide precise measurements. The world average is [57]

$$\sin 2\beta = 0.687 \pm 0.032. \quad (11.19)$$

This measurement has a four-fold ambiguity in β , which can be resolved by a global fit mentioned below. Experimentally, the two-fold ambiguity $\beta \rightarrow \pi/2 - \beta$ (but not $\beta \rightarrow \pi + \beta$) can be resolved by a time-dependent angular analysis of $B^0 \rightarrow J/\psi K^{*0}$ [84,85] or a time-dependent Dalitz plot analysis of $B^0 \rightarrow \bar{D}^0 h^0$ ($h^0 = \pi^0, \eta, \omega$) with $\bar{D}^0 \rightarrow K_S^0 \pi^+ \pi^-$ [86]. The latter gives the better sensitivity and disfavors the solutions with $\cos 2\beta < 0$ at the 97% CL, consistent with the global CKM fit result.

The $b \rightarrow c\bar{c}d$ mediated transitions, such as $B^0 \rightarrow J/\psi \pi^0$ and $B^0 \rightarrow D^{(*)+} D^{(*)-}$, also measure approximately $\sin 2\beta$. However, the dominant component of $b \rightarrow d$ penguin

10 11. CKM quark-mixing matrix

amplitude has different CKM phase ($V_{tb}^*V_{td}$) than the tree amplitude ($V_{cb}^*V_{cd}$), and their magnitudes are of the same order in λ . Therefore, the effect of penguins could be large, resulting in $S_f \neq -\eta_f \sin 2\beta$ and $C_f \neq 0$. These decay modes have also been measured by *BABAR* and *Belle*. The world averages [57], $S_{J/\psi\pi^0} = -0.69 \pm 0.25$, $S_{D^+D^-} = -0.29 \pm 0.63$, and $S_{D^{*+}D^{*-}} = -0.75 \pm 0.23$, are consistent with $\sin 2\beta$ obtained from $B^0 \rightarrow$ charmonium K^0 decays, and the C_f 's are also consistent with zero, although the uncertainties are sizable.

11.3.2.2. Penguin dominated modes:

The $b \rightarrow s\bar{q}q$ penguin dominated decays have the same CKM phase as the $b \rightarrow c\bar{c}s$ tree level decays, up to corrections suppressed by λ^2 , since $V_{tb}^*V_{ts} = -V_{cb}^*V_{cs}[1 + \mathcal{O}(\lambda^2)]$. Therefore, decays such as $B^0 \rightarrow \phi K^0$ and $\eta' K^0$ provide $\sin 2\beta$ measurements in the SM. If new physics contributes to the $b \rightarrow s$ loop diagrams and has a different weak phase, it would give rise to $S_f \neq -\eta_f \sin 2\beta$ and possibly $C_f \neq 0$. Therefore, the main interest in these modes is not simply to measure $\sin 2\beta$, but to search for new physics. Measurements of many other decay modes in this category, such as $B \rightarrow \pi^0 K_S^0$, $K_S^0 K_S^0 K_S^0$, etc., have also been performed by *BABAR* and *Belle*. The results and their uncertainties are summarized in Fig. 12.3 and Table 12.1 of Ref. [81].

11.3.3. α / ϕ_2 :

Since α is the angle between $V_{tb}^*V_{td}$ and $V_{ub}^*V_{ud}$, only time-dependent CP asymmetries in $b \rightarrow u\bar{u}d$ dominated modes can directly measure $\sin 2\alpha$, in contrast to $\sin 2\beta$, where several different transitions can be used. Since $b \rightarrow d$ penguin amplitudes have a different CKM phase than $b \rightarrow u\bar{u}d$ tree amplitudes, and their magnitudes are of the same order in λ , the penguin contribution can be sizable and makes the α determination complicated. To date, α has been measured in $B \rightarrow \pi\pi$, $\rho\pi$ and $\rho\rho$ decay modes, among which $B \rightarrow \rho\rho$ has the best precision.

11.3.3.1. $B \rightarrow \pi\pi$:

It is now experimentally well established that there is a sizable contribution of $b \rightarrow d$ penguin amplitudes in $B \rightarrow \pi\pi$ decays. Then $S_{\pi^+\pi^-}$ in the time-dependent $B^0 \rightarrow \pi^+\pi^-$ analysis no longer measures $\sin 2\alpha$, but

$$S_{\pi^+\pi^-} = \sqrt{1 - C_{\pi^+\pi^-}^2} \sin(2\alpha + 2\Delta\alpha), \quad (11.20)$$

where $2\Delta\alpha$ is the phase difference between $e^{2i\gamma}\bar{A}_{\pi^+\pi^-}$ and $A_{\pi^+\pi^-}$. The value of $\Delta\alpha$, hence α , can be extracted using the isospin relations among the amplitudes of $B^0 \rightarrow \pi^+\pi^-$, $B^0 \rightarrow \pi^0\pi^0$, and $B^+ \rightarrow \pi^+\pi^0$ decays [87],

$$\frac{1}{\sqrt{2}} A_{\pi^+\pi^-} + A_{\pi^0\pi^0} - A_{\pi^+\pi^0} = 0, \quad (11.21)$$

and a similar one for the $\bar{A}_{\pi\pi}$'s. This method utilizes the fact that a pair of pions in $B \rightarrow \pi\pi$ decay must be in a zero angular momentum state, and then, because of

Bose statistics, they must have even isospin. Consequently, $\pi^0\pi^\pm$ is in a pure isospin-2 state, while the penguin amplitudes only contribute to the isospin-0 final state. The latter does not hold for the electroweak penguin amplitudes, but their effect is expected to be small. The isospin analysis uses the world averages [57] $S_{\pi^+\pi^-} = -0.50 \pm 0.12$, $C_{\pi^+\pi^-} = -0.37 \pm 0.10$, the branching fractions of all three modes, and the direct CP asymmetry $C_{\pi^0\pi^0} = -0.28_{-0.40}^{+0.39}$. This analysis leads to 16 mirror solutions for $0 \leq \alpha < 2\pi$. Because of this, and the sizable experimental error of the $B^0 \rightarrow \pi^0\pi^0$ rate and CP asymmetry, only a loose constraint on α can be obtained at present, $0^\circ < \alpha < 17^\circ$ and $73^\circ < \alpha < 180^\circ$ at 68% CL.

11.3.3.2. $B \rightarrow \rho\rho$:

The decay $B^0 \rightarrow \rho^+\rho^-$ contains two vector mesons in the final state, which in general is a mixture of CP -even and CP -odd components. Therefore, it was thought that extracting α from this mode would be complicated.

However, the longitudinal polarization fractions (f_L) in $B^+ \rightarrow \rho^+\rho^0$ and $B^0 \rightarrow \rho^+\rho^-$ decays were measured to be close to unity [88], which implies that the final states are almost purely CP -even. Furthermore, $\mathcal{B}(B^0 \rightarrow \rho^0\rho^0) < 1.1 \times 10^{-6}$ at 90% CL [89] is much smaller than $\mathcal{B}(B^0 \rightarrow \rho^+\rho^-) = (26.4_{-6.4}^{+6.1}) \times 10^{-6}$ and $\mathcal{B}(B^+ \rightarrow \rho^+\rho^0) = (26.2_{-3.7}^{+3.6}) \times 10^{-6}$, which implies that the effect of the penguin diagrams is small. The isospin analysis using the world averages [57], $S_{\rho^+\rho^-} = -0.22 \pm 0.22$ and $C_{\rho^+\rho^-} = -0.02 \pm 0.17$, and the above-mentioned branching fractions of $B \rightarrow \rho\rho$ modes gives $\alpha = (96 \pm 13)^\circ$ [90] with a mirror solution at $3\pi/2 - \alpha$. A possible small violation of Eq. (11.21) due to the finite width of the ρ [91] is neglected.

11.3.3.3. $B \rightarrow \rho\pi$:

The final state in $B^0 \rightarrow \rho^+\pi^-$ decay is not a CP eigenstate, but this decay proceeds via the same quark level diagrams as $B^0 \rightarrow \pi^+\pi^-$ and both B^0 and \bar{B}^0 can decay to $\rho^+\pi^-$. Consequently, mixing induced CP violations can occur in four decay amplitudes, $B^0 \rightarrow \rho^\pm\pi^\mp$ and $\bar{B}^0 \rightarrow \rho^\pm\pi^\mp$. The measurements of CP violation parameters for these decays, where $B^0 \rightarrow \pi^+\pi^-\pi^0$ decays are treated as quasi-two-body decays, have been made both by *BABAR* [92] and the Belle [93]. However, the isospin analysis is rather complicated and no significant model independent constraint on α has been obtained yet.

The time-dependent Dalitz plot analysis of $B^0 \rightarrow \pi^+\pi^-\pi^0$ decays permits the extraction of α with a single discrete ambiguity, $\alpha \rightarrow \alpha + \pi$, since one knows the variation of the strong phases in the interference regions of the $\rho^+\pi^-$, $\rho^-\pi^+$, and $\rho^0\pi^0$ amplitudes in the Dalitz plot [94]. The *BABAR* measurement gives $\alpha = (113_{-17}^{+27} \pm 6)^\circ$ [95]. Although this constraint is moderate so far, it favors one of the mirror solutions in $B \rightarrow \rho^+\rho^-$.

Combining the above-mentioned three decay modes [90], α is constrained as

$$\alpha = (99_{-8}^{+13})^\circ. \quad (11.22)$$

A different statistical approach [96] gives similar constraint from the combination of these measurements.

12 11. CKM quark-mixing matrix

11.3.4. γ / ϕ_3 :

By virtue of Eq. (11.15), γ does not depend on CKM elements involving the top quark, so it can be measured in tree level B decays. This is an important distinction from the measurements of α and β , and implies that the direct measurements of γ are unlikely to be affected by physics beyond the SM.

11.3.4.1. $B^\pm \rightarrow DK^\pm$:

The interference of $B^- \rightarrow D^0 K^-$ ($b \rightarrow c\bar{u}s$) and $B^- \rightarrow \bar{D}^0 K^-$ ($b \rightarrow u\bar{c}s$) transitions can be studied in final states accessible in both D^0 and \bar{D}^0 decays [80]. In principle, it is possible to extract the B and D decay amplitudes, the relative strong phases, and the weak phase γ from the data.

A practical complication is that the precision depends sensitively on the ratio of the interfering amplitudes

$$r_B = \left| A(B^- \rightarrow \bar{D}^0 K^-) / A(B^- \rightarrow D^0 K^-) \right|, \quad (11.23)$$

which is around 0.1 – 0.2. The original GLW method [97,98] considers D decays to CP eigenstate final states, such as $B^\pm \rightarrow D_{CP}^{(*)}(\rightarrow \pi^+\pi^-)K^{\pm(*)}$. To alleviate the smallness of r_B and make the interfering amplitudes (which are products of the B and D decay amplitudes) comparable in magnitude, the ADS method [99] considers final states where Cabibbo-allowed \bar{D}^0 and doubly Cabibbo-suppressed D^0 decays interfere. Extensive measurements have been made by the B factories using both methods [100], but the constraints on γ are fairly weak so far.

It was realized that both D^0 and \bar{D}^0 have large branching fractions to certain three-body final states, such as $K_S\pi^+\pi^-$, and the analysis can be optimized by studying the Dalitz plot dependence of the interferences [101,102]. The best present determination of γ comes from this method. Belle [103] and BABAR [104] obtained $\gamma = 68_{-15}^{+14} \pm 13 \pm 11^\circ$ and $\gamma = 67 \pm 28 \pm 13 \pm 11^\circ$, respectively, where the last uncertainty is due to the D decay modeling. The error is sensitive to the central value of the amplitude ratio r_B (and r_B^* for the D^*K mode), for which Belle found somewhat larger central values than BABAR. The same values of $r_B^{(*)}$ enter the ADS analyses, and the data can be combined to fit for $r_B^{(*)}$ and γ . The possibility of D^0 - \bar{D}^0 mixing has been neglected in all measurements, but its effect on γ is far below the present experimental accuracy [105], unless D^0 - \bar{D}^0 mixing is due to CP -violating new physics, in which case it could be included in the analysis [106].

Combining the GLW, ADS, and Dalitz analyses [90], γ is constrained as

$$\gamma = (63_{-12}^{+15})^\circ. \quad (11.24)$$

The likelihood function of γ is not Gaussian, and the 95% CL range is $40^\circ < \gamma < 110^\circ$. Similar results are found in [96]. New results [107] reported after the completion of this review indicate a decrease of $r_B^{(*)}$, which leads to an increased error on γ .

11.3.4.2. $B \rightarrow D^{(*)\pm}\pi^\mp$:

The interference of $b \rightarrow u$ and $b \rightarrow c$ transitions can be studied in $\bar{B}^0 \rightarrow D^{(*)+}\pi^-$ ($b \rightarrow c\bar{u}d$) and $\bar{B}^0 \rightarrow B^0 \rightarrow D^{(*)+}\pi^-$ ($\bar{b} \rightarrow \bar{u}c\bar{d}$) decays and their CP conjugates, since both B^0 and \bar{B}^0 decay to $D^{(*)\pm}\pi^\mp$ (or $D^\pm\rho^\mp$, etc.). Since there are only tree and no penguin contributions to these decays, in principle, it is possible to extract from the four observable time-dependent rates the magnitudes of the two hadronic amplitudes, their relative strong phase, and the weak phase between the two decay paths, which is $2\beta + \gamma$.

A complication is that the ratio of the interfering amplitudes is very small, $r_{D\pi} = A(B^0 \rightarrow D^+\pi^-)/A(\bar{B}^0 \rightarrow D^+\pi^-) = \mathcal{O}(0.01)$ (and similarly for $r_{D^*\pi}$ and $r_{D\rho}$), and therefore it has not been possible to measure it. To obtain $2\beta + \gamma$, $SU(3)$ flavor symmetry and dynamical assumptions have been used to relate $A(\bar{B}^0 \rightarrow D^-\pi^+)$ to $A(\bar{B}^0 \rightarrow D_s^-\pi^+)$, so this measurement is not model independent at present. The amplitude ratio is larger in the analogous B_s decays to $D_s^\pm K^\mp$, where it will be possible to measure it and model independently extract $\gamma - 2\beta_s$ at LHCb, as proposed in Ref. [108]. Combining the $D^\pm\pi^\mp$, $D^{*\pm}\pi^\mp$ and $D^\pm\rho^\mp$ measurements [109] gives $\sin(2\beta + \gamma) = 0.8_{-0.24}^{+0.18}$, consistent with the previously discussed results for β and γ .

11.4. Global fit in the Standard Model

Using the independently measured CKM elements mentioned in the previous sections, the unitarity of the CKM matrix can be checked. We obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9992 \pm 0.0011$ (1st row), $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 0.968 \pm 0.181$ (2nd row), and $|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 1.001 \pm 0.005$ (1st column), respectively. For the second row, a more stringent check is obtained from the measurement of $\sum_{u,c,d,s,b} |V_{ij}|^2$ in Sec.11.2.4 minus the sum in the first row above: $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.003 \pm 0.027$. These provide strong tests of the unitarity of the CKM matrix. The sum of the three angles of the unitarity triangle, $\alpha + \beta + \gamma = (184_{-15}^{+20})^\circ$, is also consistent with the SM expectation.

The CKM matrix elements can be most precisely determined by a global fit that uses all available measurements and imposes the SM constraints (*i.e.*, three generation unitarity). There are several approaches to combining the experimental data. CKMfitter [90,6] and Ref. [110] (which develops [111,112] further) use frequentist statistics with different presentations of the theoretical errors, while UTfit [96,113] uses a Bayesian approach. These approaches provide similar results [114].

The constraints implied by the unitarity of the three generation CKM matrix significantly reduce the allowed range of some of the CKM elements. The fit for the Wolfenstein parameters defined in Eq. (11.4) gives

$$\begin{aligned} \lambda &= 0.2272 \pm 0.0010, & A &= 0.818_{-0.017}^{+0.007}, \\ \bar{\rho} &= 0.221_{-0.028}^{+0.064}, & \bar{\eta} &= 0.340_{-0.045}^{+0.017}, \end{aligned} \quad (11.25)$$

These values are obtained using the method of Refs. [6,90], while using the prescription of Refs. [96,113] gives $\lambda = 0.2262 \pm 0.0014$, $A = 0.815 \pm 0.013$, $\bar{\rho} = 0.235 \pm 0.031$, and $\bar{\eta} = 0.349 \pm 0.020$. The allowed ranges of the magnitudes of all nine CKM elements are

14 11. CKM quark-mixing matrix

Figure 11.2: Constraints on the $\bar{\rho}, \bar{\eta}$ plane. The shaded areas have 95% CL. See full-color version on color pages at end of book.

$$V_{\text{CKM}} = \begin{pmatrix} 0.97383^{+0.00024}_{-0.00023} & 0.2272^{+0.0010}_{-0.0010} & (3.96^{+0.09}_{-0.09}) \times 10^{-3} \\ 0.2271^{+0.0010}_{-0.0010} & 0.97296^{+0.00024}_{-0.00024} & (42.21^{+0.10}_{-0.80}) \times 10^{-3} \\ (8.14^{+0.32}_{-0.64}) \times 10^{-3} & (41.61^{+0.12}_{-0.78}) \times 10^{-3} & 0.999100^{+0.000034}_{-0.000004} \end{pmatrix}, \quad (11.26)$$

and the Jarlskog invariant is $J = (3.08^{+0.16}_{-0.18}) \times 10^{-5}$.

Fig. 11.2 illustrates the constraints on the $\bar{\rho}, \bar{\eta}$ plane from various measurements and the global fit result. The shaded 95% CL regions all overlap consistently around the global fit region, though the consistency of $|V_{ub}/V_{cb}|$ and $\sin 2\beta$ is not very good, as mentioned previously.

11.5. Implications beyond the SM

If the constraints of the SM are lifted, K , B and D decays and mixings are described by many more parameters than just the four CKM parameters and the W , Z and quark masses. The most general effective Lagrangian at lowest order contains around a hundred flavor changing operators, and the observable effects of interactions at the weak-scale or above are encoded in their coefficients. For example, Δm_d , $\Gamma(B \rightarrow \rho\gamma)$, and $\Gamma(B \rightarrow X_d \ell^+ \ell^-)$ are all proportional to $|V_{td}V_{tb}^*|^2$ in the SM, however, they may receive unrelated contributions from new physics. Similar to the measurements of $\sin 2\beta$ from tree- and loop-dominated modes, such overconstraining measurements of the magnitudes and phases of CKM elements provide excellent sensitivity to new physics. Another very clean test of the SM can come from future measurements of $\mathcal{B}(K_L^0 \rightarrow \pi^0 \nu \bar{\nu})$ and $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu})$. These loop induced decays are sensitive to new physics and will allow a determination of β independent of its value measured in B decays [115].

Not all CP -violating measurements can be interpreted as constraints on the $\bar{\rho}, \bar{\eta}$ plane. Besides the angles in Eq. (11.15), it is also useful to define $\beta_s = \arg(-V_{ts}V_{tb}^*/V_{cs}V_{cb}^*)$, which is the small, λ^2 -suppressed, angle of a “squashed” unitarity triangle obtained by taking the scalar product of the second and third columns. It is the phase between B_s mixing and $b \rightarrow c\bar{c}s$ decays, and $\sin 2\beta_s$ can be measured via time-dependent CP violation in $B_s \rightarrow J/\psi\phi$, similar to $\sin 2\beta$ in $B \rightarrow J/\psi K^0$. Checking if β_s agrees with its SM prediction, $\sin 2\beta_s = 0.036 \pm 0.003$ [116,90], is an equally important test of the theory.

In the kaon sector, both CP -violating observables ϵ and ϵ' are tiny, so models in which all sources of CP violation are small were viable before the B -factory measurements. Since the measurement of $\sin 2\beta$ we know that CP violation can be an $\mathcal{O}(1)$ effect, and it is only flavor mixing that is suppressed between the three quark generations. Thus, many models with spontaneous CP violation are excluded. Model independent statements for the constraints imposed by the CKM measurements on new physics are hard to make, because most models that allow for new flavor physics contain a large number of new parameters. For example, the flavor sector of the MSSM contains 69 CP -conserving parameters and 41 CP -violating phases (*i.e.*, 40 new ones) [117].

In a large class of models the unitarity of the CKM matrix is maintained, and the dominant new physics effect is a contribution to the $B^0-\bar{B}^0$ mixing amplitude [118], which can be parameterized as $M_{12} = M_{12}^{\text{SM}}(1 + h_d e^{i\sigma_d})$. While the constraints on h_d and σ_d are significant (before the measurements of γ and α they were not), new physics with a generic weak phase may still contribute to M_{12} at order 20% of the SM. Measurements unimportant for the SM CKM fit, such as the CP asymmetry in semileptonic decays, play a role in constraining such extensions of the SM [116]. Similar results for the constraints on new physics in K^0 and B_s^0 mixing are discussed in Refs. [113,119].

The CKM elements are fundamental parameters, so they should be measured as precisely as possible. The overconstraining measurements of CP asymmetries, mixing, semileptonic, and rare decays have started to severely constrain the magnitudes and phases of possible new physics contributions to flavor changing interactions. When new particles are observed at the LHC, it will be important to know the flavor parameters as precisely as possible to understand the underlying physics.
